National Park Service
Natural Resource Program Center
Fort Collins, Colorado
The Natural Resource Publication series addresses natural resource topics of interest and applicability to a broad readership in the National Park Service and to others in the management of natural resources, including the scientific community, the public, and the NPS conservation and environmental constituencies. Manuscripts are peer-reviewed to ensure the information is scientifically credible, technically accurate, appropriately written for the intended audience, and is designed and published in a professional manner.

Natural Resource Reports are the designated medium for disseminating high priority, current natural resource management information with managerial application. The series targets a general, diverse audience, and may contain NPS policy considerations or address sensitive issues of management applicability. Examples of the diverse array of reports published in this series include vital signs monitoring plans; monitoring protocols; “how to” resource management papers; proceedings of resource management workshops or conferences; annual reports of resource programs or divisions of the Natural Resource Program Center; resource action plans; fact sheets; and regularly-published newsletters.

Views, statements, findings, conclusions, recommendations and data in this report are solely those of the author(s) and do not necessarily reflect views and policies of the U.S. Department of the Interior, National Park Service. Mention of trade names or commercial products does not constitute endorsement or recommendation for use by the National Park Service.

This report is available from the Natural Resource Publications Management website:

I. Introduction

Purpose

Climate change presents significant risks to our nation’s natural and cultural resources. Although climate change was once believed to be a future problem, there is now unequivocal scientific evidence that our planet’s climate system is warming (IPCC 2007a). While many people understand that human emissions of greenhouse gases have contributed to recent observed climate changes, fewer are aware of the specific impacts these changes will bring. This document is part of a series of bioregional summaries that provide key scientific findings about climate change and impacts to protected areas. The information is intended to provide a basic understanding of the science of climate change, known and expected impacts to resources and visitor experience, and actions that can be taken to mitigate and adapt to change. The statements may be used to communicate with managers, frame interpretive programs, and answer general questions to the public and the media. They also provide helpful information to consider in developing sustainability strategies and long-term management plans.

Audience

The Talking Points documents are primarily intended to provide park and refuge area managers and staff with accessible, up-to-date information about climate change and climate change impacts to the resources they protect.

Organizational Structure

Following the Introduction are three major sections of the document: a Regional Section that provides information on changes to Alaska Boreal and Artic, a section outlining No Regrets Actions that can be taken now to mitigate and adapt to climate changes, and a general section on Global Climate Change. The Regional Section is organized around seven types of changes or impacts, while the Global Section is arranged around four topics.

Regional Section

- Temperature
- The Water Cycle (including snow, ice, lake levels, sea levels and sea level rise, and ocean acidification)
- Vegetation (plant cover, species range shifts, and phenology)
- Wildlife (aquatic, marine, and terrestrial animals, range shifts, invasive species, migration, and phenology)
- Disturbance (including range shifts, plant cover, plant pests and pathogens, fire, flooding, and erosion)
- Cultural Resources
- Visitor Experience

Global Section

- Temperature and Greenhouse Gases
- Water, Snow, and Ice
- Vegetation and Wildlife
- Disturbance

Information contained in this document is derived from the published results of a range of scientific research including historical data, empirical (observed) evidence, and model projections (which may use observed or theoretical relationships). While all of the statements are informed by science, not all statements carry the same level of confidence or scientific certainty. Identifying uncertainty is an important part of science but can be a major source of confusion for decision makers and the public. In the strictest sense, all scientific results carry some level of uncertainty because the scientific method can only “prove” a hypothesis to be false. However, in a practical world, society routinely elects to make choices and select options for actions that carry an array of uncertain outcomes.

The statements in this document have been organized to help managers and their staffs differentiate among current levels of uncertainty in climate change science. In doing so, the document aims to be consistent with the language and approach taken in the Fourth Assessment on Climate Change reports by the Intergovernmental Panel on Climate Change (IPCC). However, this document discriminates among only three different levels of uncertainty and does not attempt to ascribe a specific probability to any particular level. These are qualitative rather than quantitative categories, ranked from greatest to least certainty, and are based on the following:

- “What scientists know” are statements based on measurable data and historical records. These are statements for which scientists generally have high confidence and agreement because they are based on actual measurements and observations. Events under this category have already happened or are very likely to happen in the future.

- “What scientists think is likely” represents statements beyond simple facts; these are derived from some level of reasoning or critical thinking. They result from projected trends, well tested climate or ecosystem models, or empirically observed relationships (statistical comparisons using existing data).

- “What scientists think is possible” are statements that use a higher degree of inference or deduction than the previous categories. These are based on research about processes that are less well understood, often involving dynamic interactions among climate and complex ecosystems. However, in some cases, these statements represent potential future conditions of greatest concern, because they may carry the greatest risk to protected area resources.
II. Climate Change Impacts to Alaska Boreal and Arctic Bioregions

The Boreal and Arctic Bioregion that is discussed in this section is shown in the map to the right. A list of parks and refuges for which this analysis is most useful is included on the next page. To help the reader navigate this section, each category is designated by color-coded tabs on the outside edge of the document.

Summary

Alaska is a huge state spanning 375 million acres and occupying nearly one-fifth of the land area of the contiguous 48 states. More than half of the coastline of the entire United States is in Alaska. Due to the great size and geographically diverse nature of Alaska, two bioregional documents were produced: “Boreal and Arctic” and “Alaska Maritime and Transitional.” In Alaska, the vast majority of the land is public; with approximately 222 million acres (approximately 60%) designated federal lands and another 90 million acres (approximately 24%) in state ownership. There are 17 National Park Service (NPS) areas in Alaska covering over 54 million acres; this represents two-thirds of the land in the entire National Park system. Wrangell-St. Elias is the largest NPS unit at over 13 million acres in size. There are 16 National Wildlife Refuges in Alaska totaling over 76 million acres, representing approximately 80% of the entire National Wildlife Refuge system. The two national forests in Alaska encompass nearly 22 million acres; Tongass National Forest is the largest United States Forest Service unit, with nearly 17 million acres. The Bureau of Land Management manages almost 78 million acres in Alaska.
Climate changes in the Boreal and Arctic bioregion include increased mean, minimum, and maximum annual and seasonal temperatures, especially in the spring and winter, resulting in earlier spring budding, an increase in the length of the growing season, and an increase in the annual numbers of snow-free and frost-free days. Hotter, drier summers contribute to drought stress in the boreal forest, leading to reduced tree growth, changes in rates of carbon sequestration, and increased disturbance from fires and insect outbreaks. In addition, shrub expansion into Arctic tundra is altering forage availability for caribou and other wildlife. Additional climate change impacts include changes to regional hydrology, including decreased spatial extent of glaciers and sea ice, and increased sea surface temperatures. Secondary effects include shifts in plankton availability in the Bering Sea, which in turn is impacting the distribution and population dynamics of fish, seabird, and wildlife species.

A. TEMPERATURE

What scientists know…

• Mean annual temperatures in Alaska increased an average 1.7°C over the last six decades, with a general warming rate of 0.16 to 0.37°C per decade from 1951 to 2001 (Alaska Climate Research Center et al. 2009; Hartmann and Wendler 2005).

• From 1949 to 2009, regional mean annual temperatures for the Arctic, Interior, and West Coast of Alaska increased by 1.4 to 2.5°C (2.5 to 4.5°F) and the greatest change in mean seasonal temperatures (2.3 to 4.9°C, 4.1 to 8.8°F) was observed in the winter (Alaska Climate Research Center 2010).

• Maximum temperature increases were observed throughout Alaska; the greatest increases were observed during the spring with an average of 0.46°C (0.83°F) per decade (Keyser et al. 2000). Average maximum temperatures increased per decade 0.14°C (0.25°F) in the summer and 0.24°C (0.43°F) in the winter (Keyser et al. 2000).

• Alaska-wide minimum temperatures have warmed proportionally more than mean or maximum temperatures; the lowest (coldest) temperatures have warmed more than the highest (hottest) temperatures. (Stafford et al. 2000; Alaska Climate Research Center, Geophysical Institute 2009). Per decade average minimum temperatures increased by 0.23°C (0.41°F) during the summer and 0.35°C (0.63°F) during the winter, and spring minimum temperatures increased an average of 0.47°C (0.85°F) per decade. (Keyser et al. 2000).

• Alaska’s mean annual diurnal temperature ranges (difference between maximum and minimum temperatures) decreased 0.3°C (0.5°F) between 1949 and 1998. In the Interior and the Arctic, the winter mean diurnal temperature ranges decreased by 0.6 to 0.9°C (1.1 to 1.6°F) respectively. Both summer and autumn showed slight increases in mean diurnal temperature ranges (Stafford et al. 2000).

• Fairbanks experienced a general warming trend from 1906 to 2006. The mean annual temperature increased 1.4°C (2.5°F) compared to 0.8°C (1.4°F) worldwide. Temperatures increased during the winter, spring, and summer seasons, while autumn showed a slight decrease in temperature. The number of days with very low temperatures (less than -40°C) has decreased, on average, from 14 to 8 days annually (Wendler and Shulski 2009).

• An increase in the length of the growing season in Fairbanks was observed from 1906 to 2006. For the 0°C (32°F) freezing point, the growing period increased from 85 to 123 days (45%). At -2.2°C (28°F), the temperature threshold for frost-resistant plants, the growing season increased from 113 to 144 days, or 27% (Wendler and Shulski 2009).

• From 1982 to 2008, summer tundra land temperatures, as measured by the summer warmth index (sum of the monthly mean temperatures that are above freezing), increased 24% for the northern hemisphere as a whole; the North America Arctic tun-
• Models predict that the mean number of frost days in the Boreal and Arctic bioregion will decrease by between 20 and 40 days per year by the end of the 21st century, as compared with trends from 1961 to 1990 (Meehl et al. 2004).

• Models based on mid-range (A1B) emissions scenarios project that by 2091, average monthly temperatures for Barrow, where the Inupiat Heritage Center is located, will increase by 1.1 to 2.8°C (2.0°F to 5.0°F) during the summer months and 8.9 to 14.6°C (16.0 to 26.0°F) during the winter months (Scenarios Network for Alaska Planning 2009a). These models also predict that temperatures in Kotzebue, the closest large community to the Western Arctic National Parklands, will increase 3 to 5 times more in the winter than in the summer by the year 2091. Two months that historically had average temperatures below freezing will increase to above freezing by 2061 (Scenarios Network for Alaska Planning 2009b).

**What scientists think is possible…**

• Annual mean temperatures are predicted to increase at an average rate of 0.56°C (1.0°F) per decade for Alaskan National Park units and the Yukon Flats National Wildlife Refuge. Average winter temperatures for the national park units are predicted to increase by 5.6 to 7.8°C (10.1 to 14.0°F) by 2080 (Rupp and Loya 2009a, b, c, d, e, f, g, h).

• Modeling indicates that average annual temperatures in the Bering Land Bridge National Preserve, Denali National Park and Preserve, Yukon-Charley Rivers National Preserve, and Yukon Flats National Wildlife Refuge are predicted to shift from below freezing to above freezing during the 21st century (Rupp and Loya 2009; Rupp and Loya 2009a, b, h).

**What scientists think is likely….**

• Since the mid-1960s, the melt date (date of final snowmelt) in northern Alaska has advanced by about 8 days (Stone et al. 2002).

• The majority of Alaskans polled anticipate that global climate change will result in more comfortable temperatures (Leiserowitz and Craciun 2006).

• By the end of the century, the growing season in Yukon Flats National Wildlife Refuge could be 1 month longer than it is currently (Rupp and Loya 2009).
What scientists know....

- All Alaskan glaciers below ~1500 m (4,905 ft) in elevation are melting, and many of Alaska’s 100,000 glaciers (including tidewater formations) are retreating and/or thinning (Molnia 2007, 2008). In Denali National Park and Preserve many of the glaciers are retreating an average of 66 ft per year (Adema et al. 2007).

- The melting rate of glaciers throughout Alaska has increased in recent decades, as has their contribution to sea level rise (Dyurgerov and Meier 2000; Larsen et al. 2007a). From the mid 1990s to the early 2000s, the rate of glacial thinning in Alaska tripled compared to the mid 1950s to mid-1970s time period; the loss of ice during this period was equivalent to nearly twice the estimated annual loss of ice from the Greenland Ice Sheet. Over the last half of the 20th century, Alaska glaciers contributed the largest single measured glaciological contribution to sea level, with a total annual volume change of $-52 \pm 15 \text{ km}^3/\text{year} (12.3 \pm 3.6 \text{ miles}^3)$ water equivalent, which equates to a rise in sea level of 0.14 mm $\pm$ 0.04 mm/year, (0.006 $\pm$ 0.002 in/year) (Arendt et al. 2002).

- Changes in sea ice in both the Arctic Ocean and the Bering Sea have been observed; for example, ice cover on the Bering Sea shelf decreased significantly from 1954 to 2006 (Mueter and Litzow 2008), and a net thinning of the Arctic sea ice by -0.6 m (1.97 feet) was observed between 2004 and 2008. In addition, there has been a decrease in the amount of perennial sea ice, and the 2009 summer sea ice minimum was the third-lowest recorded since 1979, and 2007 was the lowest (Perovich et al. 2009).

- The Arctic Ocean sea ice melt season has increased by 6.4 days per decade between 1979 and 2007 (Hansen 2010).

- Spring break-up on the Tanana River has advanced by 0.71 days per decade coinciding with increases in spring surface temperature in interior Alaska (80+ years of data) (Keyser et al. 2000).

- Snow patterns at Barrow, Alaska, have changed in the past five decades. From 1972 to 2000, the duration of the snow-free period increased by 3 to 6 days per decade, and the first week in spring without snow cover shifted to 3 to 5 days earlier per decade (Dye 2002). In addition, the snow melt date has advanced by 8 days since the mid-1960s (Stone et al., 2002).

- Observed decreases in snow and ice extent reduce the albedo (proportion of solar radiation reflected by a surface) of the surrounding land surface (Richter-Menge and Overland 2009). With a reduction in the albedo of northern Alaska, both from reduction of snow and loss of sea ice, more of the sun’s energy will be absorbed rather than reflected, creating a positive feedback loop of increasing temperatures. This positive feedback leads to more ice melt, a delay in fall ice formation, and reduced sea ice volume (Francis et al. 2009).
The mean discharge was observed in North American Arctic rivers from 2000 to 2007, as compared with the 1973-1999 average (Shiklomanov 2009).

- From the 1950s to 2000s, closed-basin ponds in boreal regions decreased in area and number; the area of subarctic ponds decreased by 4 to 31%, whereas Arctic ponds did not show a marked change in pond area (Riordan et al. 2006). During the same time period, 22 out of 24 ponds being studied near Council, Alaska decreased in area (Yoshikawa and Hinzman 2003).

- In 2004, a retrogressive thaw slump (slope failure resulting from thawing permafrost) occurred on the upper Selawik River in the Selawik National Wildlife Refuge as a result of thawing permafrost. The Selawik slump is the largest of its kind in North America. It is increasing in size and projected to increase for decades. The slump covers an area of 8.7 acres and as of 2009 has deposited approximately 12.6 million ft³ of sediment into the Selawik river (Crosby 2009).

- As permafrost thaws, thermokarst features, such as ponds, form. The thawing also results in an increase in surface water runoff, increased ocean storage of freshwater, increased albedo, and an increase in the depth of the active layer of the permafrost (soil overlaying the permafrost that experiences seasonal thawing and freezing) (Francis et al. 2009).

What scientists think is likely....

- Acidification of Alaska’s oceans is occurring at a faster rate than in tropical waters. Cold water, shallow continental shelves, and high productivity of Alaska’s marine waters facilitate the increased absorption of CO2, reduced deep water circulation, and decomposition, respectively; all contribute to increased acidification compared to other regions (University of Alaska Fairbanks 2009).

- Models predict that precipitation will increase in all national park units in this bioregion from 12 to 33% in the summers and 25 to 65% in the winter months.
Due to increased evapotranspiration (the transport of water into the atmosphere from surfaces, including soils and vegetation) from temperature increases and lengthened growing seasons, summer and fall seasons will be drier than they are currently (Rupp and Loya 2009a, b, c, d, e, f, g, h). By 2035, Yukon Flats National Wildlife Refuge is predicted to be 10% drier; by 2075, 25% drier in summer and fall (Rupp and Loya 2009).

Evidence from studies conducted in southeast Alaska indicates that as watersheds become deglaciated and plant succession occurs, inputs of organic carbon and inorganic nitrogen into streams will be altered, thereby changing the land-to-ocean fluxes of nutrients (Hood and Durelle 2008).

As temperatures increase in the Arctic, the sea ice extent decreases. Reduced sea ice extent will have an effect on land temperature, potentially extending up to 1,500 km (930 miles) inland; higher temperatures on land will contribute to more rapid permafrost thawing and further loss of sea ice. Water vapor will also likely increase as a result, leading to increased precipitation (Lawrence et al. 2008, Francis et al. 2009).

C. VEGETATION

What scientists think is possible....

• Based on a meta analysis of studies examining phenological shifts (shifts in life cycle processes), species at higher latitudes are more sensitive to climatic change than species that exist at lower latitudes (Root et al. 2003).

• Climate has demonstrably affected terrestrial ecosystems through changes in the seasonal timing of life-cycle events (phenology), plant growth responses (primary production), and biogeographic distribution (Parmesan 2006; Field 2007). Statistically significant shifts in Northern Hemisphere vegetation phenology, productivity, and distribution have been observed and are attributed to 20th century climate changes (Walther 2002; Parmesan and Yohe 2003; Parmesan 2006).

• Between 1980 and 2000, vegetation responses mainly to changes in temperature resulted in an observed trend toward earlier spring budburst and increased maximum leaf area at high northern latitudes (Lucht et al. 2002). In the Arctic, there is evidence of earlier plant greening and later plant senescence (seasonal die-off) (Griffith et al. 2001, Stow et al. 2003).

• Based on over 40 years of data collected across Alaska, the growing season has lengthened by an average of 2.6 days per 10 years (Keyser et al. 2000). Onset of the growing season occurred 5.6 days earlier between 1982 and 1991, 3.9 days later between 1991 and 1992 (attributed to the eruption of Mount Pinatubo), and 1.7 days earlier between 1992 and 1999 (Tucker et al. 2001). On average, an advance in average leaf onset date of 1.10 days per 10 years was observed between the 1950s and 1990s (Keyser et al. 2000).
Increases in temperature and CO₂ between the 1980s and the 2000s resulted in increased photosynthetic activity or growth on tundra ecosystems, including a 7% increase in Arctic tundra and 11% in North American tundra (Goetz et al. 2005; Walker et al. 2009).

Net primary production (photosynthesis) for both aspen (Populus tremuloides) and white spruce (Picea glauca) stands in Alaska and northwestern Canada increased by 20% with the advance in the start of the growing season (Keyser et al. 2000). However, tree-ring records indicate that radial growth in interior white spruce stands has decreased with increasing temperature, due to temperature-induced drought stress (Barber et al. 2000).

Tree growth, measured from tree-ring chronologies, increased from 1900–1950 at almost all sites at and near alpine and arctic treelines; significant declines in tree growth were common after 1950 in all sites but those in the Alaska Range, and declines were most common in the warmer and drier sites at or near alpine and arctic treeline (Lloyd and Fastie 2002).

Based on current and historical photographs from the Arctic, a widespread increase in shrub abundance, primarily along hillsides and valleys, occurred from the 1940s to 2000s (Sturm et al. 2001; Tape et al. 2006).

Arctic wetland emissions of methane, a powerful greenhouse gas, increased by 31% between 2003 and 2007 due to temperature increases (Bloom et al. 2010).

What scientists think is likely....

• Land use changes in the boreal region may result in greater soil carbon losses than in other areas. If forests are converted to agricultural land, the resulting carbon losses could induce a positive feedback to climatic warming (Grünzweig et al. 2004).

• In the Arctic, warming air temperatures may result in large areas of tundra being converted to shrubland, amplified by a positive feedback cycle in which shrub abundance leads to deeper snow, which promotes higher winter soil temperatures, greater microbial activity, and more plant-available nitrogen; high levels of soil nitrogen in turn favor shrub growth the following summer (Sturm et al. 2005).

• Drought stress in the boreal forests limits carbon uptake. If this trend continues, the carbon sequestration capacity of these forests may decrease over time (Barber et al. 2000).

• Modeling exercises indicate that boreal tree ecotones exhibit varying responses to warming, and therefore treeline advancement will vary spatially and temporally (Lloyd et al. 2003).

• During nine years of experimental climate change manipulations on tundra vegetation, there was a loss of 30 to 50% of the plant species being studied; evergreen shrubs and understory forbs (rarer species) declined more strongly than other species or disappeared completely (Chapin et al. 1995). A “greenhouse climate” simulation also indicates a reduction in the areas occupied by forbs, lichens, and mosses, and a northward shift of shrubs and forested areas, particularly evergreen forests (Kaplan et al. 2003).

What scientists think is possible....

• All members of the genus Picea except P. sitchensis, and Pinus banksiana exhibited stronger-than-expected declines in growth rates with warmer temperatures, likely due to conditions such as direct...
temperature stress, temperature-mediated drought stress, and in some cases air pollution. (Lloyd and Bunn 2007).

- Treelines will advance into areas currently occupied by Arctic tundra, altering ecosystem nutrient availability (Burkett et al. 2005).

- A variety of future climate scenarios for vegetation distribution in interior Alaska show black spruce (Picea mariana) as the emergent dominant vegetation type. A scenario of warming coupled with increasing wildfire activity resulted in the greatest expansion of black spruce (Calef et al. 2005).

- A model of the effects of climate warming on Arctic plant communities showed different responses in the short term (2 years), longer term (50 to 75 years) and at 200 years. After 200 years, community composition was not typical of vegetation today. The model showed an increase in lichen, decrease in sedges, and increases in deciduous and evergreen shrubs (Epstein et al. 2000).

- Models predict that by 2050, warmer, drier conditions and associated increased wildfire activity will alter the vegetation composition of Yukon Flats National Wildlife Refuge and similar lands. A decline in the proportion of mature trees and shift to earlier successional plant communities was predicted, with deciduous forests replacing white and black spruce forests, which could experience a 50% decline (Rupp and Loya 2009).

- Thirty percent of the Pacific brant (Branta bernicla nigricans) population, a migratory goose species, now spends their winters in Alaska instead of migrating south to Mexico, whereas in the past only 10% of the population wintered in Alaska. This shift in migration patterns corresponds with warming regional temperatures (Ward et al. 2009).

- Thirty percent of the Pacific brant (Branta bernicla nigricans) population, a migratory goose species, now spends their winters in Alaska instead of migrating south to Mexico, whereas in the past only 10% of the population wintered in Alaska. This shift in migration patterns corresponds with warming regional temperatures (Ward et al. 2009).

- Hatch dates for geese and spectacled eiders on the Yukon-Kusokwim delta have advanced by 5 to 10 days in the past 25 years. May temperatures, timing of river ice breakup, and onset of the snow-free period on the tundra are correlated with hatch dates (Fischer et al. 2009).

- Both common and thick-billed murres (Uria aalge and Uria lomvia, respectively) showed population reductions with large sea surface temperature shifts in either

---

The birthing season for moose is closely linked to climatic trends that provide the most hospitable conditions for bearing and rearing young; climate change may hinder moose calf survival by throwing this relationship out of sync. NPS Photo.
direction (Irons et al. 2008), but breeding productivity for these seabirds was found to be greater when summer sea surface temperatures were colder (Byrd et al. 2008).

- On the Pribilof Islands in the Bering Sea, red-legged and black-legged kittiwakes, small seabirds in the gull family, bred earlier and hatch dates progressed by 0.58 to 0.88 days per year between 1975 and 2006. For both species of kittiwakes, productivity appears to be higher when nesting begins earlier, when ice is abundant near foraging grounds, and in winter and spring when sea surface temperatures cool. (Byrd et al. 2008).

- The Audubon Christmas Bird count, a citizen science project, has documented that the center of the mean annual latitudinal center of abundance for over 300 bird species shifted northward nearly 35 miles (56.4 km) between 1966 and 2004. There is a significant correlation between temperature trends and shifts in the center of abundance. The mean latitudinal shift for the pine siskin, a small finch and year-round resident of southern Alaska, was approximately 288 miles (463.7 km) north (Niven and Butcher 2009).

- The Audubon Christmas Bird count, a citizen science project, has documented that the center of the mean annual latitudinal center of abundance for over 300 bird species shifted northward nearly 35 miles (56.4 km) between 1966 and 2004. There is a significant correlation between temperature trends and shifts in the center of abundance. The mean latitudinal shift for the pine siskin, a small finch and year-round resident of southern Alaska, was approximately 288 miles (463.7 km) north (Niven and Butcher 2009).

- The timing of the plankton bloom in the Bering Sea is associated with sea ice edge and extent. For example, late seasonal ice retreat supports benthic (bottom-dwelling) organisms that are an important food resource for marine species. In contrast, ice-free periods or early ice retreats support a mainly pelagic (upper ocean) ecosystem (Hunt and Stabeno 2002; Hunt et al. 2002; Overland and Stabeno 2004). An increase in air and ocean temperatures, a reduction in sea ice, reduction benthic prey populations, and an increase in pelagic fish resulted in a shift in marine mammal population distributions (Grebmeier et al. 2006).

- From 1982 to 2006, fish and invertebrate species shifted northward an average of 34 ± 6 km (21 ± 35 miles) in response to the northward retreat of the southern edge of the cold water pool on the Bering Sea shelf. A reorganization of community composition was also observed (Mueter and Litzow 2008).

What scientists think is likely:

- Changes to the terrestrial and aquatic species compositions in parks and refuges are likely to occur as ranges shift, contract, or expand. Rare species and/or communities may be at further risk, and additional species could become rare (Burns et al. 2003).

- Parks and refuges may not be able to meet their mandate of protecting current species within their boundaries, or in the case of some refuges, the species for whose habitat protection they were designed. While wildlife may be able to move northward or to higher elevations to escape some effects of climate change, federal boundaries are static (Burns et al. 2003).

- Models suggest that the distribution of the little brown bat will expand northward in Alaska in the next century in response to warming temperatures and shorter winters in its current range (Humphries et al. 2002).

- Of the 83 species of arctic and alpine birds, 72% are considered moderately or highly vulnerable to the impacts of climate change, primarily due to their long-distance migrations and their reliance on arctic and alpine habitats that are vulnerable to effects of climate change (NABCI 2010).

- As trees and shrubs encroach on areas currently occupied by tundra, arctic and alpine breeding birds’ breeding habitats may be reduced or eliminated (NABCI 2010).
Coastal seabirds such as the arctic ivory gull, *Pagophila eburnea*, aleutian tern (*Onychoprion aleuticus*), and Kittlitz’s murrelet (*Brachyramphus brevirostris*) show medium or high vulnerability to climate change due to their low reproductive potential and their reliance on marine food webs that are also threatened by climate change (NABCI 2010).

Kittlitz’s murrelets are closely associated with glaciated fjords and coastlines. With glacial retreat, important habitats will be lost and Kittlitz’s populations may decline (USFWS 2006).

Thawing permafrost may result in changes in the distribution and abundance of waterfowl, shorebirds, and gulls due to shifts in the types and locations of plant communities and changes in surface water availability; contaminants such as mercury and organic pollutants may also be released into the aquatic environment as the permafrost thaws, increasing contaminant exposure for birds that rely on the marine ecosystem for food (NABCI 2010).

Boreal forest birds will expand into the arctic as climate changes, causing new avian communities to develop (NABCI 2010).

Arctic marine mammals that are closely linked to sea ice, such as the polar bear, are predicted to be the most sensitive to climate change (based on an index of population size, geographic range, habitat specificity, diet diversity, migration, site fidelity, sensitivity to changes in sea ice, sensitivity to changes in the food web, and maximum population growth potential (Laidre et al. 2008).

As sea surface temperatures change, the distribution of plankton and forage fish will change and as a result, seabirds and marine mammal forage patterns, distribution, and population dynamics change (Hunt et al. 2002; Irons et al. 2008, Meehan et al. 1999).

In the northern Chukchi Sea and in the Canada Basin of the Arctic Ocean, an undersaturation of aragonite (a mineral essential for developing the shells or calcium-carbonate skeletons of some marine fauna) has occurred due to ocean acidification and freshwater influx from sea ice melting (Bates et al. 2009; Yamamoto-Kawai et al. 2009). Models show that high latitude ocean waters could become undersaturated with magnesium-calcite minerals of higher solubility than aragonite in less than a few decades due to ocean acidification (Andersson et al. 2008). This undersaturation has potential to cause profound shifts throughout arctic ecosystems, and may ultimately affect survival of large animals such as walruses, gray whales, and some birds as the planktonic and benthic organisms they eat become more scarce (Bates et al. 2009).

Ocean acidification is likely more rapid and severe in Alaska than in tropical waters, and will make shell building more difficult for pteropods, oysters, crabs and other shelled marine animals. It will also impact growth, reproduction, and survival of many marine organisms, includ-
ing pteropods, which make up nearly half of the pink salmon’s diet (University of Alaska Fairbanks 2009).

- Changes in marine community organization in the Bering Sea caused by warming climate and associated loss of sea ice will alter availability of snow crab and other fisheries resources (Mueter and Litzow 2008).

What scientists think is possible....

- Changes in marine community organization in the Bering Sea caused by warming climate and associated loss of sea ice will alter availability of snow crab and other fisheries resources (Mueter and Litzow 2008).

- Predicted changes in arctic vegetation from tundra to taiga and boreal forest could result in millions of geese losing nearly half of their breeding habitat (Zöckler and Lysenko 2001).

- Glacier ice worm populations, which rely on a very limited temperature range, are in danger of local extinctions in Denali National Park and Preserve and the Alaska Range as glaciers melt (Shain 2009).

- An analysis of potential climate change impacts on mammalian species in U.S. national parks indicates that with a doubling of atmospheric CO₂, about 8% of current mammalian species diversity may be lost on average. The greatest losses across all parks occurred in rodent species (44%), bats (22%), and carnivores (19%). Species are projected to decline in direct proportion to their current relative representation within parks. (Burns et al. 2003).

- The timing and synchrony of birth for moose in Denali National Park and Preserve are adaptations to long-term trends in climate that provide the most hospitable conditions to bear and rear young; climate change may decouple this relationship, hindering moose calf survival (Bowyer et al. 1998).

- In 2004, there were three instances of polar bear cannibalism in the Beaufort Sea. No other similar instances have been observed during more than 20 years of research, and researchers hypothesize that nutritional stresses related to longer ice-free seasons may have led to the incidents (Amstrup et al. 2006).

- The health of caribou and reindeer may be affected by changes in temperature and precipitation patterns. Warming could lead to an increase in insects and pests known to harass caribou. Changes in the freeze/thaw cycle may alter forage availability in late summer and winter which could decrease the carrying capacity of
caribou and reindeer. Warmer and drier summers may reduce the availability of succulent forage for reindeer causing nutritional stress (Babcock et al. 1998).

- Predicted shifts in forest community in Yukon Flats National Wildlife Refuge could result in less suitable habitat for caribou (fewer spruce forests over 80 years old), but potentially increased habitat for moose (increased deciduous forest) (Rupp and Loya 2009).

- A retrogressive thaw slump on the upper Selawik River, Selawik NWR, is above spawning habitat for sheefish (Inconnu), an important subsistence fish. Sediment input from the slump may reduce survival of eggs developing in the gravel. Other fish habitats in permafrost-dominated areas may be similarly threatened by thaw slumps and their associated sediment input into rivers (USFWS 2009).

- Fisheries (especially for pink salmon) may see a dramatic decrease in productivity if pteropods and other crustaceans, the preferred prey of salmonids, are negatively impacted by ocean acidification (University of Alaska Fairbanks 2009).

E. DISTURBANCE

What scientists know....

- Increases in coastal shoreline erosion rates were observed in the Arctic along parts of the Alaskan Beaufort Sea. Mean annual erosion rates increased from 6.8 meters (22.3 ft) per year (1955 to 1979), to 8.7 meters (28.5 ft) per year (1979 to 2002), to 13.6 meters (44.6 ft) per year (2002 to 2007). Different erosion rates were observed in different coastal ecosystems during the earlier years of the study, but erosion rates during the later years of the study were more uniformly high (Jones et al. 2009).

- Average storm power (determined by a combination of wind speed and duration) along the coast of the Arctic Ocean increased 59% between the study periods of 1955-1978 and 1979-2001. An additional increase of 35% was observed between the 1979-2001 and 2002-2006 study periods (Jones et al. 2009).

- In interior Alaska, the most extensive wildfires burn during unusually dry years. The frequency of unusually dry years increased from once or twice a decade in the 1950s to several times a decade at the end of the 20th century (Kasischke and Turetsky 2006).

- Shifts in the North American boreal region fire regime from the 1960s and 70s to the 1980s and 90s were characterized by an increase in large fire events, resulting in a doubling of annual burned area and more than a doubling of the frequency of larger fire years (>1,000 km² or 620 mi²) (Kasischke and Turetsky 2006).

- Tundra fires generally accelerate carbon loss due to both direct burning and subsequent warming of soils, causing higher rates of decomposition. One study found that for at least two decades following a tundra fire, the area was a carbon source, not sink (Oechel 1999).
Coastal erosion led to the collapse of this house in Shishmaref, a Native Alaskan community that is seeking to relocate due to increasingly severe coastal disturbances. NPS Photo.

- A tundra site was monitored at intervals up to 24 years following a wildfire. An increase in shrub abundance and little recovery of Sphagnum moss or fruticose lichens were observed (Racine et al. 2004).

- An increase in vascular plant cover and in particular shrub cover, was observed on several 20+ year old fire sites in Noatak National Preserve (Racine et al. 2006).

- Permafrost thickness did not return to its pre-fire thickness at several sites following a fire on the tundra (Racine et al. 2004).

- Insect outbreaks increase in frequency and severity with warmer temperatures (Juday et al. 2004). Warming trends have coincided with increases in spruce budworm in Alaska in recent years and suggest that populations could continue to move northward with continued climate warming (Juday 1998; Juday et al. 2004).

- The majority of Alaskans polled anticipate that global climate change will cause increased flooding, worse storms, fewer salmon, and the extinction of the polar bear (Leiserowitz and Craciun 2006).

**What scientists think is likely....**

- Impacts such as vegetation population shifts, major permafrost thawing, soil decomposition, and surface subsidence have been observed that were observed in the decades following a major tundra fire event suggest that major tundra fires in other permafrost areas could result in similar impacts, which could even accelerate the predicted effects of climate warming (Racine et al. 2004).

- Research in Gates of the Arctic National Park and Preserve found that fire, in the short-term, may be an important tool for helping to maintain yellow-cheeked vole populations, as fire creates new burrowing habitat and aids in the growth of forage (Swanson 1997).

- Due to ocean acidification, there has been a decrease in sound absorption. Based on current projections of future pH values for the oceans, a decrease in sound absorption of 40% is expected by mid-century (Hester et al. 2008).

- As sea ice diminishes, increasing commercial ship traffic through the Bering and Beaufort Seas and across the Northwest Passage will increase the risk, and potentially the environmental damage, from accidents, oil spills, and cargo spills (ACIA 2004).

**What scientists think is possible....**

- Ichthyophonus, a fish parasite that causes mortality in fish populations and is easily and rapidly spread among fishes, infected 45% of Chinook salmon in the Yukon River and about 30% of the salmon in the Tanana River between 1999 and 2003. Warming water temperatures may have contributed to these levels of infection, as the parasite was not reported to affect salmon in these rivers before 1985 (Kocan et al. 2004).

- Model simulations suggest that a warming climate may result in greater number of fires and as much as a 22% increase in the regional area burned, as the result of both increased vegetation flammability in direct response to increased temperatures and expansion of forested areas into previously treeless tundra (Dale et al. 2001; Rupp et al. 2000).

- Model projections of wildfire activity in the Yukon Flats National Wildlife Refuge estimate that 11,000km² (4,228 mi², or
25%) of the refuge will burn by 2040, with some areas experiencing multiple fires within that time frame. In addition, between 2010 and 2080 70% of the refuge is predicted to experience new burns, with a total cumulative burned area of 42,000 km$^2$ by 2080 (Rupp and Loya 2009).

**CULTURAL RESOURCES**

*What scientists know....*

- Sea level rise, increased storm surges, and the impacts of permafrost erosion to infrastructure have begun to impact Native Alaskan communities, diverting resources from subsistence activities and in some cases requiring relocation of entire communities (Callaway 2007).

- Relocating indigenous communities represents a large financial cost for governments, but also impacts the communities themselves, potentially resulting in loss of integral cultural elements such as access to traditional use areas for subsistence activities, loss of history and sense of intact community, and potential loss of social networks and extended kin support (Callaway 2007).

- In Kotzebue, a mostly native community in northern Alaska, effects of climate change have been noticeable, but mixed. Changes in temperature, storm surges, and ice cover have led to easier whitefish and clam harvests, better spotted seal and caribou hunting by boat, easier access to arctic foxes, and better access to driftwood. Conversely, these same changes have also resulted in a shorter ice fishing season, reduced access to and from Kotzebue for transfer of goods and services, increased erosion and flooding, and dangerous travel conditions associated with thawing or incomplete freezing of ice (Whiting 2002).

- Some traditional subsistence practices are more expensive and time-consuming than in the recent past, due to difficult hunting conditions associated with climate change impacts. These changes can place a strain on subsistence communities, and in some cases can be a deterrent to engaging in traditional hunting at all; for example, as sea ice conditions change, marine mammals may follow sea ice retreat, altering their distribution and taking them out of range for some hunters (Berman and Kofinas 2004; Callaway 2007; Hanna 2007).

- According to the Alaska Department of Resources, Division of Lands, the winter tundra travel season on the Arctic North Slope has decreased from about 200 days in the 1970s to about 120 days in the early 2000s. Reliable travel over the frozen tundra enables natural resource development, access to subsistence sites, and travel between villages (Bradwell et al. 2004).

- The majority of Alaskans polled believe that global warming will seriously impact their families, communities, plants, and animals. Many believe that it will have serious impacts to Alaska within a decade (Leiserowitz and Craciun 2006).

*What scientists think is likely....*

- As glaciers and ice melt, cultural resources may be uncovered. Artifacts have been recovered from ice patches in Wrangell-St. Elias National Park. For example, five prehistoric sites were identified that contained artifacts ranging in age from 370 to 2880 years before present. Such artifacts can provide unprecedented glimpses into the lives of ancient people (Dixon et al. 2007).

- Subsistence communities have expressed concerns about increased pollution and its potential effects on the natural environment’s ability to respond to climate change. For example, because heavy metals and other contaminants bio-accumu-
late up the food chain, there are concerns that marine mammals and other animals harvested for subsistence could be sources of contaminants for hunters and their families as changes in circulatory patterns of water and air bring contaminants into the natural system (Callaway 1999). Researchers have found contaminants and heavy metals in animals harvested for subsistence in the Arctic (Cooper et al. 2000; Dehn et al. 2006).

**What scientists think is possible....**

- Climate change may affect people’s ability to conduct subsistence harvests due to changes in wildlife distribution and availability. Subsistence harvesting activities are linked to the health of rural residents in several ways, including the physical exertion of a hunt that promotes mental and physical well being, the nutritional value of harvested food items compared to store-bought food, and the value of maintaining a traditional diet (Callaway 1999).

- Modeling of several feedback loops that take place within the Arctic hydrologic system (including those centered around cloud cover, water vapor, surface air temperature, precipitation, sea ice, marine productivity, human well-being, and land cover) shows that in a seasonally ice-free Arctic Ocean model, the complexity of the system is greatly reduced, affecting the function of the feedback loops and resulting in a decrease in human well-being in all scenarios (Francis et al. 2009).

- Some indigenous people in northern Alaska are concerned that as polar bears have an increasingly difficult time accessing prey and finding appropriate shelter for reproduction and protection, they may be more likely to approach villages and encounter humans. (ACIA 2004).

**VISITOR EXPERIENCE**

**What scientists know....**

- Glaciers, a main tourist attraction in many parks, are disappearing. This is happening throughout Alaska, including at national parks such as Wrangell St.-Elias, Denali and Kenai Fjords (Adema et al. 2007; Dyrurgerov and Meier 2000; Larsen et al. 2007a; Molnia 2007; Rupp and Loya 2009).

- With increasing temperatures and more snow-free days, the length of the potential summer tourist season in Alaska is increasing (Alaska Climate Research Center 2009; Dye 2002).

**What scientists think is likely....**

- Locations of climatically ideal tourism conditions are likely to shift toward higher latitudes under projected change, and as a consequence spatial and temporal redistribution of tourism activities may occur. The effects of these changes will depend greatly on the flexibility demonstrated by institutions and tourists as they react to climate change (Amelung et al. 2007).

- Increase in coastal erosion along the Bering Sea and Arctic Ocean could erode coastlines, affecting travel and tourist destinations (Smith and Levasseur 2003).

**What scientists think is possible....**

- Warmer temperatures and a reduction in sea ice may open up areas of the Northwest Passage and the Northern Sea Route to transportation. If the Northwest Passage becomes ice-free for summer travel, an increase in visitation to the Arctic via cruise ship is expected (ACIA 2004).

- Damage to roads, buildings, and other infrastructure is predicted with climate change, due largely to permafrost thawing (ACIA 2004; Smith and Levasseur 2003). Damage could increase future costs for Alaska’s public infrastructure from 3.6 to 6.1 billion dollars (10% to 20%) by 2030 to 5.6 to 7.6 billion dollars (10% to 12%) by 2080 (Larsen et al. 2007b).

- The majority of Alaskans polled believe that tourism will increase as a result of global climate change (Leiserowitz and Craciun 2006).
Individuals, businesses, and agencies release carbon dioxide (CO₂), the principal greenhouse gas, through burning of fossil fuels for electricity, heating, transportation, food production, and other day-to-day activities. Increasing levels of atmospheric CO₂ have measurably increased global average temperatures, and are projected to cause further changes in global climate, with severe implications for vegetation, wildlife, oceans, water resources, and human populations. Emissions reduction – limiting production of CO₂ and other greenhouse gases - is an important step in addressing climate change. It is the responsibility of agencies and individuals to find ways to reduce greenhouse gas emissions and to educate about the causes and consequences of climate change, and ways in which we can reduce our impacts on natural resources. There are many simple actions that each of us can take to reduce our daily carbon emissions, some of which will even save money.

### Agencies Can...

**Improve sustainability and energy efficiency**

- Use energy efficient products, such as ENERGY STAR® approved office equipment, appliances and light bulbs.

- Initiate an energy efficiency program to monitor energy use in buildings. Provide guidelines for reducing energy consumption.

- Convert to renewable energy sources such as solar or wind generated power.

- Specify “green” designs for construction of new or remodeled buildings.

- Include discussions of climate change in park Environmental Management System.

- Conduct an emissions inventory and set goals for CO₂ reduction.

- Provide alternative transportation options such as employee bicycles and shuttles for within-unit commuting.

- Provide hybrid electric or propane-fueled vehicles for official use, and impose fuel standards for park vehicles. Reduce the number and/or size of park vehicles and boats to maximize efficiency.

- Provide a shuttle service or another form of alternate transportation for visitor and employee travel to and within the unit.

- Provide incentives for use of alternative transportation methods.

- Use teleconferences and webinars or other forms of modern technology in place of travel to conferences and meetings.

**Implement Management Actions**

- Engage and enlist collaborator support (e.g., tribes, nearby agencies, private landholders) in climate change discussions, responses, and mitigation.

- Develop strategies and identify priorities for managing uncertainty surrounding climate change effects in parks and refuges.

- Build a strong partnership-based foundation for future conservation efforts.

- Identify strategic priorities for climate change efforts when working with partners.

- Incorporate anticipated climate change impacts, such as decreases in lake levels, rising sea levels, or changes in vegetation and wildlife, into management plans.

- Encourage research and scientific study in park units and refuges.

- Design long-term monitoring projects and management activities that do not rely...
Restoring damaged landscapes

- Restoration efforts are important as a means for enhancing species’ ability to cope with stresses and adapt to climatic and environmental changes. Through restoration of natural areas, we can lessen climate change impacts on species and their habitats. These efforts will help preserve biodiversity, natural resources, and recreational opportunities.

- Strategically focus restoration efforts, both in terms of the types of restoration undertaken and their national, regional, and local scale and focus, to help maximize resilience.

- Restore and conserve connectivity within habitats, protect and enhance instream flows for fish, and maintain and develop access corridors to climate change refugia.

Educate staff and the public

- Post climate change information in easily accessible locations such as on bulletin boards and websites.

- Provide training for park and refuge employees and partners on effects of climate change on resources, and on dissemination of climate change knowledge to the public.

- Support the development of region, park, or refuge-specific interpretive products on the impacts of climate change.

- Incorporate climate change research and information in interpretive and education outreach programming.

- Distribute up-to-date interpretive products (e.g., the National Park Service-wide Climate Change in National Parks brochure).

- Develop climate change presentations for local civic organizations, user and partner conferences, national meetings, etc.

- Incorporate climate change questions and answers into Junior Ranger programs.

• Solely on fossil fuel-based transportation and infrastructure.

• Incorporate products and services that address climate change in the development of all interpretive and management plans.

• Take inventory of the facilities/boundaries/species within your park or refuge that may benefit from or be vulnerable to climate change mitigation or adaptation activities.

• Participate in gateway community sustainability efforts.

• Recognize the value of ecosystem services that an area can provide, and manage the area to sustain these services. Conservation is more cost-effective than restoration and helps maintain ecosystem integrity.

• Provide recycling options for solid waste and trash generated within the park.

• Anticipate potential landscape and sea-level changes when designing new or replacement facilities and infrastructure, including positioning new facilities to avoid or mitigate impact from sea level rise or permafrost thawing.

• Work with native communities to identify climate refugia as special places for sustaining traditional subsistence living.

Park Service employees install solar panels at San Francisco Maritime National Historical Park (Top); At the National Mall, Park Service employees use clean-energy transportation to lead tours; NPS photos.
The Climate Friendly Parks Program is a joint partnership between the U.S. Environmental Protection Agency and the National Park Service. Climate Friendly Parks from around the country are leading the way in the effort to protect our parks' natural and cultural resources and ensure their preservation for future generations; NPS image.

“Humankind has not woven the web of life. We are but one thread within it. Whatever we do to the web, we do to ourselves. All things are bound together. All things connect.” —Chief Seattle

• Help visitors make the connection between reducing greenhouse gas emissions and resource stewardship.

• Encourage visitors to use public or non-motorized transportation to and around parks.

• Encourage visitors to reduce their carbon footprint in their daily lives and as part of their tourism experience.

Individuals can...

• In the park or refuge park their car and walk or bike. Use shuttles where available. Recycle and use refillable water bottles. Stay on marked trails to help further ecosystem restoration efforts.

• At home, walk, carpool, bike or use public transportation if possible. A full bus equates to 40 fewer cars on the road. When driving, use a fuel-efficient vehicle.

• Do not let cars idle - letting a car idle for just 20 seconds burns more gasoline than turning it off and on again.

• Replace incandescent bulbs in the five most frequently used light fixtures in the home with bulbs that have the ENERGY STAR® rating. If every household in the U.S. takes this one simple action we will prevent greenhouse gas emissions equivalent to the emissions from nearly 10 million cars, in addition to saving money on energy costs.

Reduce, Reuse, Recycle, Refuse

• Use products made from recycled paper, plastics and aluminum - these use 55-95% less energy than products made from scratch.

• Purchase a travel coffee mug and a reusable water bottle to reduce use of disposable products (Starbucks uses more than 1 billion paper cups a year).

• Carry reusable bags instead of using paper or plastic bags.

• Recycle drink containers, paper, newspapers, electronics, and other materials. Bring recyclables home for proper disposal when recycle bins are not available. Rather than taking old furniture and clothes to the dump, consider “recycling” them at a thrift store.

• Keep an energy efficient home. Purchase ENERGY STAR® appliances, properly insulate windows, doors and attics, and lower the thermostat in the winter and raise it in the summer (even 1-2 degrees makes a big difference). Switch to green power generated from renewable energy sources such as wind, solar, or geothermal.

• Buy local goods and services that minimize emissions associated with transportation.

• Encourage others to participate in the actions listed above.

IV. Global Climate Change

The IPCC is a scientific intergovernmental, international body established by the World Meteorological Organization (WMO) and by the United Nations Environment Programme (UNEP). The information the IPCC provides in its reports is based on scientific evidence and reflects existing consensus viewpoints within the scientific community. The comprehensiveness of the scientific content is achieved through contributions from experts in all regions of the world and all relevant disciplines including, where appropriately documented, industry literature and traditional practices, and a two stage review process by experts and governments.

Definition of climate change: The IPCC defines climate change as a change in the state of the climate that can be identified (e.g. using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer. All statements in this section are synthesized from the IPCC report unless otherwise noted.

A. Temperature and Greenhouse Gases

*What scientists know…*

- Warming of the Earth’s climate system is unequivocal, as evidenced from increased air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level (Figure 1).

- In the last 100 years, global average surface temperature has risen about 0.74°C over the previous 100-year period, and the rate of warming has doubled from the previous century. Eleven of the 12 warmest years in the instrumental record of global surface temperature since 1850 have occurred since 1995 (Figure 1).

- Although most regions over the globe have experienced warming, there are regional variations: land regions have warmed faster than oceans and high northern latitudes have warmed faster than the tropics. Average Arctic temperatures have increased at almost twice the global rate in the past 100 years, primarily because loss of snow and ice results in a positive feedback via increased absorption of sunlight by ocean waters (Figure 2).

- Over the past 50 years widespread changes in extreme temperatures have been observed, including a decrease in cold days and nights and an increase in the frequency of hot days, hot nights, and heat waves.

- Winter temperatures are increasing more rapidly than summer temperatures, particularly in the northern hemisphere, and...
there has been an increase in the length of the frost-free period in mid- and high-latitude regions of both hemispheres.

- Climate change is caused by alterations in the energy balance within the atmosphere and at the Earth’s surface. Factors that affect Earth’s energy balance are the atmospheric concentrations of greenhouse gases and aerosols, land surface properties, and solar radiation.

- Global atmospheric concentrations of greenhouse gases have increased significantly since 1750 as the result of human activities. The principal greenhouse gases are carbon dioxide (CO₂), primarily from fossil fuel use and land-use change; methane (CH₄) and nitrous oxide (N₂O), primarily from agriculture; and halocarbons (a group of gases containing fluorine, chlorine or bromine), principally engineered chemicals that do not occur naturally.

- Direct measurements of gases trapped in ice cores demonstrate that current CO₂ and CH₄ concentrations far exceed the natural range over the last 650,000 years and have increased markedly (35% and 148% respectively), since the beginning of the industrial era in 1750.

- Both past and future anthropogenic CO₂ emissions will continue to contribute to warming and sea level rise for more than a millennium, due to the time scales required for the removal of the gas from the atmosphere.
• Warming temperatures reduce oceanic uptake of atmospheric CO₂, increasing the fraction of anthropogenic emissions remaining in the atmosphere. This positive carbon cycle feedback results in increasingly greater accumulation of atmospheric CO₂ and subsequently greater warming trends than would otherwise be present in the absence of a feedback relationship.

• There is very high confidence that the global average net effect of human activities since 1750 has been one of warming.

• Scientific evidence shows that major and widespread climate changes have occurred with startling speed. For example, roughly half the north Atlantic warming during the last 20,000 years was achieved in only a decade, and it was accompanied by significant climatic changes across most of the globe (NRC 2008).

**What scientists think is likely**

• Anthropogenic warming over the last three decades has likely had a discernible influence at the global scale on observed changes in many physical and biological systems.

• Average temperatures in the Northern Hemisphere during the second half of the 20th century were very likely higher than during any other 50-year period in the last 500 years and likely the highest in at least the past 1300 years.

• Most of the warming that has occurred since the mid-20th century is very likely due to increases in anthropogenic greenhouse gas concentrations. Furthermore, it is extremely likely that global changes observed in the past 50 years can only be explained with external (anthropogenic) forcings (influences) (Figure 2).

• There is much evidence and scientific consensus that greenhouse gas emissions will continue to grow under current climate change mitigation policies and development practices. For the next two decades a warming of about 0.2°C per decade is projected for a range of emissions scenarios; afterwards, temperature projections increasingly depend on specific emissions scenarios (Table 1).

• It is very likely that continued greenhouse gas emissions at or above the current rate will cause further warming and result in changes in the global climate system that will be larger than those observed during the 20th century.

• It is very likely that hot extremes, heat waves and heavy precipitation events will become more frequent. As with current trends, warming is expected to be greatest over land and at most high northern latitudes, and least over the Southern Ocean (near Antarctica) and the northern North Atlantic Ocean.

**What scientists think is possible**

• Global temperatures are projected to increase in the future, and the magnitude of temperature change depends on specific emissions scenarios, and ranges from a 1.1°C to 6.4°C increase by 2100 (Table 1).

Notes: a) Temperatures are assessed best estimates and likely uncertainty ranges from a hierarchy of models of varying complexity as well as observational constraints. b) Temperature changes are expressed as the difference from the period 1980-1999. To express the change relative to the period 1850-1899 add 0.5°C. c) Year 2000 constant composition is derived from Atmosphere-Ocean General Circulation Models (AOGCMs) only.
Figure 3. Sea ice concentrations (the amount of ice in a given area) simulated by the GFDL CM2.1 global coupled climate model averaged over August, September and October (the months when Arctic sea ice concentrations generally are at a minimum). Three years (1885, 1985 & 2085) are shown to illustrate the model-simulated trend. A dramatic reduction of summertime sea ice is projected, with the rate of decrease being greatest during the 21st century portion. The colors range from dark blue (ice free) to white (100% sea ice covered); Image courtesy of NOAA GFDL.

• Anthropogenic warming could lead to changes in the global system that are abrupt and irreversible, depending on the rate and magnitude of climate change.

• Roughly 20-30% of species around the globe could become extinct if global average temperatures increase by 2 to 3°C over pre-industrial levels.

B. Water, Snow, and Ice

What scientists know...

• Many natural systems are already being affected by increased temperatures, particularly those related to snow, ice, and frozen ground. Examples are decreases in snow and ice extent, especially of mountain glaciers; enlargement and increased numbers of glacial lakes; decreased permafrost extent; increasing ground instability in permafrost regions and rock avalanches in mountain regions; and thinner sea ice and shorter freezing seasons of lake and river ice (Figure 3).

• Annual average Arctic sea ice extent has shrunk by 2.7% per decade since 1978, and the summer ice extent has decreased by 7.4% per decade. Sea ice extent during the 2007 melt season plummeted to the lowest levels since satellite measurements began in 1979, and at the end of the melt season September 2007 sea ice was 39% below the long-term (1979-2000) average (NSIDC 2008)(Figure 4).

• Global average sea level rose at an average rate of 1.8 mm per year from 1961 to 2003 and at an average rate of 3.1 mm per year from 1993 to 2003. Increases in sea level since 1993 are the result of the following contributions: thermal expansion, 57%; melting glaciers and ice caps, 28%, melting polar ice sheets, 15%.

• The CO₂ content of the oceans increased by 118 ± 19 Gt (1 Gt = 109 tons) between A.D. 1750 (the end of the pre-industrial period) and 1994 as the result of uptake of anthropogenic CO₂ emissions from the atmosphere, and continues to increase by about 2 Gt each year (Sabine et al. 2004; Hoegh-Guldberg et al. 2007). This
increase in oceanic CO2 has resulted in a 30% increase in acidity (a decrease in surface ocean pH by an average of 0.1 units), with observed and potential severe negative consequences for marine organisms and coral reef formations (Orr et al. 2005; McNeil and Matear 2007; Riebesell et al. 2009).

- Oceans are noisier due to ocean acidification reducing the ability of seawater to absorb low frequency sounds (noise from ship traffic and military activities). Low-frequency sound absorption has decreased over 10% in both the Pacific and Atlantic over the past 200 years. An assumed additional pH drop of 0.3 (due to anthropogenic CO2 emissions) accompanied with warming will lead to sound absorption below 1 kHz being reduced by almost half of current values (Hester et al. 2008).

- Even if greenhouse gas concentrations are stabilized at current levels thermal expansion of ocean waters (and resulting sea level rise) will continue for many centuries, due to the time required to transport heat into the deep ocean.

- Observations since 1961 show that the average global ocean temperature has increased to depths of at least 3000 meters, and that the ocean has been taking up over 80% of the heat added to the climate system.

- Hydrologic effects of climate change include increased runoff and earlier spring peak discharge in many glacier- and snow-fed rivers, and warming of lakes and rivers.

- Runoff is projected to increase by 10 to 40% by mid-century at higher latitudes and in some wet tropical areas, and to decrease by 10 to 30% over some dry regions at mid-latitudes and dry tropics. Areas in which runoff is projected to decline face a reduction in the value of the services provided by water resources.

- Precipitation increased significantly from 1900 to 2005 in eastern parts of North and South America, northern Europe, and northern and central Asia. Conversely, precipitation declined in the Sahel, the Mediterranean, southern Africa, and parts of southern Asia (Figure 5).

**What scientists think is likely....**

- Widespread mass losses from glaciers and reductions in snow cover are projected to accelerate throughout the 21st century, reducing water availability and changing seasonality of flow patterns.

- Model projections include contraction of snow cover area, widespread increases in depth to frost in permafrost areas, and Arctic and Antarctic sea ice shrinkage.

- The incidence of extreme high sea level has likely increased at a broad range of sites worldwide since 1975.

- Based on current model simulations it is very likely that the meridional overturning circulation (MOC) of the Atlantic Ocean will slow down during the 21st century; nevertheless regional temperatures are predicted to increase. Large-scale and persistent changes in the MOC may result in changes in marine ecosystem productivity,
fisheries, ocean CO2 uptake, and terrestrial vegetation.

- Globally the area affected by drought has likely increased since the 1970s and the frequency of extreme precipitation events has increased over most areas.

- Future tropical cyclones (typhoons and hurricanes) are likely to become more intense, with larger peak wind speeds and increased heavy precipitation. Extra-tropical storm tracks are projected to move poleward, with consequent shifts in wind, precipitation, and temperature patterns.

- Increases in the amount of precipitation are very likely in high latitudes and decreases are likely in most subtropical land regions, continuing observed patterns (Figure 5).

- Increases in the frequency of heavy precipitation events in the coming century are very likely, resulting in potential damage to crops and property, soil erosion, surface and groundwater contamination, and increased risk of human death and injury.

**What scientists think is possible…**

- Arctic late-summer sea ice may disappear almost entirely by the end of the 21st century (Figure 3).

- Current global model studies project that the Antarctic ice sheet will remain too cold for widespread surface melting and gain mass due to increased snowfall. However, net loss of ice mass could occur if dynamical ice discharge dominates the ice sheet mass balance.

- Model-based projections of global average sea level rise at the end of the 21st century range from 0.18 to 0.59 meters, depending on specific emissions scenarios (Table 2). These projections may actually underestimate future sea level rise because they do not include potential feedbacks or full effects of changes in ice sheet flow.

- Partial loss of ice sheets and/or the thermal expansion of seawater over very long time scales could result in meters of sea level rise, major changes in coastlines and inundation of low-lying areas, with greatest effects in river deltas and low-lying islands.

**C. Vegetation and Wildlife**

**What scientists know…**

- Temperature increases have affected Arctic and Antarctic ecosystems and predator species at high levels of the food web.

- Changes in water temperature, salinity, oxygen levels, circulation, and ice cover in marine and freshwater ecosystems have resulted in shifts in ranges and changes in algal, plankton, and fish abundance in high-latitude oceans; increases in algal and zooplankton abundance in high-latitude and high-altitude lakes; and range shifts and earlier fish migrations in rivers.

- High-latitude (cooler) ocean waters are currently acidified enough to start dissolving pteropods; open water marine snails

---

</table>
which are one of the primary food sources of young salmon and mackerel (Fabry et al. 2008, Feely et al. 2008). In lower latitude (warmer) waters, by the end of this century Humboldt squid’s metabolic rate will be reduced by 31% and activity levels by 45% due to reduced pH, leading to squid retreating at night to shallower waters to feed and replenish oxygen levels (Rosa and Seibel 2008).

- A meta-analysis of climate change effects on range boundaries in Northern Hemisphere species of birds, butterflies, and alpine herbs shows an average shift of 6.1 kilometers per decade northward (or 6.1 meters per decade upward), and a mean shift toward earlier onset of spring events (frog breeding, bird nesting, first flowering, tree budburst, and arrival of migrant butterflies and birds) of 2.3 days per decade (Parmesan and Yohe 2003).

- Poleward range shifts of individual species and expansions of warm-adapted communities have been documented on all continents and in most of the major oceans of the world (Parmesan 2006).

- Satellite observations since 1980 indicate a trend in many regions toward earlier greening of vegetation in the spring linked to longer thermal growing seasons resulting from recent warming.

- Over the past 50 years humans have changed ecosystems more rapidly and extensively than in any previous period of human history, primarily as the result of growing demands for food, fresh water, timber, fiber, and fuel. This has resulted in a substantial and largely irreversible loss of Earth’s biodiversity

- Although the relationships have not been quantified, it is known that loss of intact ecosystems results in a reduction in ecosystem services (clean water, carbon sequestration, waste decomposition, crop pollination, etc.).

**What scientists think is likely…**

- The resilience of many ecosystems is likely to be exceeded this century by an unprecedented combination of climate change, associated disturbance (flooding, drought, wildfire, insects, ocean acidification) and other global change drivers (land use change, pollution, habitat fragmentation, invasive species, resource over-exploitation) (Figure 6).

- Exceedance of ecosystem resilience may be characterized by threshold-type responses such as extinctions, disruption of ecological interactions, and major changes in ecosystem structure and disturbance regimes.

- Net carbon uptake by terrestrial ecosystems is likely to peak before mid-century and then weaken or reverse, amplifying climate changes. By 2100 the terrestrial biosphere is likely to become a carbon source.

- Increases in global average temperature above 1.5 to 2.5°C and concurrent atmospheric CO2 concentrations are projected to result in major changes in ecosystem structure and function, species’ ecological interactions, and species’ geographical ranges. Negative consequences are projected for species biodiversity and ecosystem goods and services.

- Model projections for increased atmospheric CO2 concentration and global temperatures significantly exceed values for at least the past 420,000 years, the period during which more extant marine organisms evolved. Under expected 21st century conditions it is likely that global warming and ocean acidification will compromise carbonate accretion, resulting in less diverse reef communities and failure of some existing carbonate reef structures. Climate changes will likely exacerbate local stresses from declining water quality and overexploitation of key species (Hoegh-Guldberg et al. 2007).

- Ecosystems likely to be significantly impacted by changing climatic conditions include:

  i. Terrestrial – tundra, boreal forest, and mountain regions (sensitivity to warming); Mediterranean-type ecosystems and tropical rainforests (decreased rainfall)
Figure 6. Examples of impacts associated with projected global average surface warming. Upper panel: Illustrative examples of global impacts projected for climate changes (and sea level and atmospheric CO\textsubscript{2}, where relevant) associated with different amounts of increase in global average surface temperature in the 21\textsuperscript{st} century. The black lines link impacts; broken-line arrows indicate impacts continuing with increasing temperature. Entries are placed so that the left-hand side of text indicates the approximate level of warming that is associated with the onset of a given impact. Quantitative entries for water scarcity and flooding represent the additional impacts of climate change relative to the conditions projected across the range of SRES scenarios A1FI, A2, B1 and B2. Adaptation to climate change is not included in these estimations. Confidence levels for all statements are high. Lower panel: Dots and bars indicate the best estimate and likely ranges of warming assessed for the six SRES marker scenarios for 2090-2099 relative to 1980-1999 (IPCC 2007a).
ii. Coastal – mangroves and salt marshes (multiple stresses)

iii. Marine – coral reefs (multiple stresses); sea-ice biomes (sensitivity to warming)

**What scientists think is possible...**

- Approximately 20% to 30% of plant and animal species assessed to date are at increased risk of extinction with increases in global average temperature in excess of 1.5 to 2.5°C.

- Endemic species may be more vulnerable to climate changes, and therefore at higher risk for extinction, because they may have evolved in locations where paleo-climatic conditions have been stable.

- Although there is great uncertainty about how forests will respond to changing climate and increasing levels of atmospheric CO₂, the factors that are most typically predicted to influence forests are increased fire, increased drought, and greater vulnerability to insects and disease (Brown 2008).

- If atmospheric CO₂ levels reach 450 ppm (projected to occur by 2030–2040 at the current emissions rates), reefs may experience rapid and terminal decline worldwide from multiple climate change-related direct and indirect effects including mass bleaching, ocean acidification, damage to shallow reef communities, reduction of biodiversity, and extinctions. (Veron et al. 2009). At atmospheric CO₂ levels of 560 ppmv, calcification of tropical corals is expected to decline by 30%, and loss of coral structure in areas of high erosion may outpace coral growth. With unabated CO₂ emissions, 70% of the presently known reef locations (including cold-water corals) will be in corrosive waters by the end of this century (Riebesell, et al. 2009).

**What scientists think is likely...**

- The health status of millions of people is projected to be affected by climate change, through increases in malnutrition; increased deaths, disease, and injury due to extreme weather events; increased burden of diarrheal diseases; increased cardiorespiratory disease due to higher concentrations of ground-level ozone in urban areas; and altered spatial distribution of vector-borne diseases.

**What scientists think is possible...**

- The most vulnerable industries, settlements, and societies are generally those in coastal and river flood plains, those whose economies are closely linked with climate-sensitive resources, and those in areas prone to extreme weather events.

- By 2080-2090 millions more people than today are projected to experience flooding due to sea level rise, especially those in the low-lying megadeltas of Asia and Africa and on small islands.

- Climate change affects the function and operation of existing water infrastructure and water management practices, aggravating the impacts of population growth, changing economic activity, land-use change, and urbanization.

**What scientists know...**

- Climate change currently contributes to the global burden of disease and premature death through exposure to extreme events and changes in water and air quality, food quality and quantity, ecosystems, agriculture, and economy (Parry et al. 2007).

- The health status of millions of people is projected to be affected by climate change, through increases in malnutrition; increased deaths, disease, and injury due to extreme weather events; increased burden of diarrheal diseases; increased cardiorespiratory disease due to higher concentrations of ground-level ozone in urban areas; and altered spatial distribution of vector-borne diseases.

- Risk of hunger is projected to increase at lower latitudes, especially in seasonally dry and tropical regions.
